

## Part 4: Sampling

(Chapter 4 of *DSP First*)

### Lecture Notes

We have already discussed the basic idea of sampling a continuous-time signal to obtain a discrete-time signal. Here's a reminder:

#### Sampling:

Sampling a continuous-time signal  $x(t)$  produces a discrete-time signal

$$x[n] = x(nT_s)$$

where  $T_s$  = "sampling interval",  $f_s = 1/T_s$  = "sampling rate" or "sampling frequency"

(It might seem more realistic to describe sampling as  $x[n] = x(nT_s + \tau)$ , where  $\tau$  is some time "offset". However, "time zero" is just some arbitrary reference time, so we can assume it is chosen so that  $\tau=0$ .)

#### Interpolation/reconstruction

This part of the course is mostly about about the reverse problem, namely, converting a discrete-time signal to a continuous-time signal, which is called "interpolation" or "reconstruction" or "discrete-time to continuous-time conversion".

We begin with a discussion of engineering tasks that require sampling, and see that some, but not all, of them involve converting discrete-time signals to continuous-time. We will then focus mainly on one of these tasks.

**Sampling is the first component of an analog-to-digital converter**

**Analog-to-digital conversion:**

Three components: sampler, quantizer and binary encoder

Analog to digital conversion is abbreviated A/D conversion or ADC. It is also called "digitization".

**Quantization:**

The "quantizer" takes the input sample  $x[n]$  and "rounds" it to the nearest of a finite set of "quantization levels".

The quantization levels are ordinarily of the form

$$a, a+\Delta, a+2\Delta, \dots, a+(M-1)\Delta$$

where  $M$  is the number of levels,  $a$  is the first level, and  $\Delta$  is the "level spacing".

Example:  $M = 8, a = 0, \Delta = 0.1$

**Binary encoding:**

The "binary encoder" assigns a distinct binary sequence, called a *codeword*, to each quantization level.

If  $M = 2^m$ , then the codewords have  $m$  bits. It is often said that this is an "m-bit quantizer" or that this quantizer "encodes with m-bits per sample".

Example continued:  $m = 3$

**Example:** A continuous-time signal  $x(t)$ , its samples  $x[n]$ , the quantized samples  $\hat{x}[n]$ , and the bits produced by the encoder  $b[m]$ .

(plots to be shown here)

**Tasks requiring analog-to-digital conversion:****A. Digitization for digital storage/transmission**

e.g. for speech, audio, images, video, ...

**digital-to-analog conversion**

The goals are to get as good a reconstructed continuous-time signal as possible, using as few bits/second as possible.

Example continued: The interpolated output of the digital-to-analog converter  $\hat{x}(t)$ .

(plot to be shown here)

**B. Signal recovery (noise reduction)**

e.g. for radio signal recovery, noisy audio signals, ...

The goal is to have the reconstructed signal  $\hat{s}(t)$  be as similar as possible to  $s(t)$ .

**C. Signal detection**

e.g. for radar, sonar, dollar change machines,

The goal is to make decisions about  $s(t)$ , such as a "signal present" or "signal not present" decision, that are as reliable as possible. For this task, no digital-to-analog conversion is needed, i.e. no reconstruction of  $x(t)$  or  $s(t)$  is needed.

**D. Other**

Many other systems use sampling and/or ADC, for example, MRI and other digital imaging systems and sampled control systems.

## Discrete-Time to Continuous-Time Conversion, aka Interpolation or Reconstruction

The discussion that follows will primarily address Task A, digitization for digital storage and/or transmission. The main issue is how to convert a discrete-time signal into a continuous-time signal.

However, the discussion also has relevance to the other tasks as well as will be discussed later. Note that several of our lab assignments involve Task C, signal detection. With task B in mind, later in the course we will spend considerable time (Chapters 5-8) developing "digital filters".

### Two simple interpolators:

- a. zero-order hold (Section 4.4.3)  
(show example here)
- b. linear interpolation (Section 4.4.4)  
(show example here)

### Interpolation with pulses (Section 4.4.2):

$$\tilde{x}(t) = \sum_{n=-\infty}^{\infty} x[n] p(t-nT_s),$$

where  $p(t)$  is some basic interpolation pulse.

Examples:

- i. zero-order hold is the special case

$$p(t) = \begin{cases} 1, & -T_s/2 \leq t \leq T_s/2 \\ 0, & \text{otherwise} \end{cases} \quad (\text{show plot here})$$

- ii. linear interpolation is the special case

$$p(t) = \begin{cases} 1-|t|/T_s, & -T_s \leq t \leq T_s \\ 0, & \text{otherwise} \end{cases} \quad (\text{show plot here})$$

- iii. parabolic interpolation (Section 4.4.5)

$$p(t) = \dots \text{ see Figure 4.17, p. 103} \quad (\text{show plot here})$$

- iv. Other  $p$ 's are possible and useful.

### Other interpolators:

Given a set of samples there are infinitely many ways to interpolate. That is, there are infinitely many ways to draw a continuous-time signal that passes through the samples. All of these may be considered to be interpolations, even if they are not pulse-type interpolations. For example, a set of samples and three rather arbitrary interpolations are shown below

**Quality of the interpolated signal**

Though we won't emphasize this much, one can use MSE to measure the quality of the interpolated signal, i.e.

$$\text{MSE} = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} (x(t) - \tilde{x}(t))^2 dt .$$

**Questions:**

- Among all possible interpolators, what is best?
- Among all possible pulse-type interpolators, what is best?
- For a given type of interpolation how does quality depend on the sampling frequency  $f_s$ ?
- Is there a tradeoff between quality and complexity/cost of interpolators?

**Basic guiding principles:**

Given a discrete-time signal  $s[n]$ , a good interpolation method should produce a continuous-time signal  $s(t)$  such that

- $s(t)$  has  $s[n]$  as its samples, i.e.  $s(nT_s) = s[n]$ , for each  $n$
- $s(t)$  is as smooth as possible.

The motivation for (a) is self-evident. The motivation for (b) is a kind of Occam's razor principle, which postulates that the simplest explanation for some phenomenon is the best explanation. Here we assert that the smoothest and least fluctuating interpolation is the best interpolation, because it is in some sense the simplest. For example, in the previous figure, one can easily identify the smoothest and least fluctuating interpolation of the three shown. More generally, we look for interpolations whose spectrum is concentrated at the lowest possible frequencies, because interpolations with larger high frequency components will fluctuate more and be less smooth. With smooth interpolations in mind, parabolic interpolation is better than linear, which in turn is better than zero-order hold.

**The effect of increasing the sampling rate  $f_s$ :**

- With zero-order hold, linear interpolation, parabolic interpolation and most pulse-type interpolations, it should be intuitive that  $\tilde{x}(t)$  becomes a better approximation to  $x(t)$  as  $f_s$  increases. For example, it is intuitively clear that

$$\text{MSE} \rightarrow 0 \text{ as } f_s \rightarrow \infty$$

On the other hand, we'd prefer to be able to use as small a sampling rate as possible, because a smaller sampling rate generates fewer samples for us to have to store and/or to process. As a result, at some point MSE is sufficiently small and further increases in the sampling rate are not worthwhile, i.e. when increasing the sampling rate, there is a point of diminishing returns.

- Surprisingly, however, there is one particular choice of  $p(t)$  that creates perfect interpolations. And, surprisingly,  $f_s$  need not grow without limit. Instead it is only required that  $f_s$  be larger than twice the frequency of all spectral components of the signal. This remarkable result stems from the "sampling theorem".

**The Sampling Theorem** (Sections 4.1.2 and 4.5)

If the sampling frequency  $f_s$  is greater than the twice the frequency of all spectral components of the signal  $x(t)$ , then

$$x(t) = \sum_{n=-\infty}^{\infty} x(nT_s) p^*(t-nT_s)$$

where

$$p^*(t) = \frac{\sin(\frac{\pi}{T_s}t)}{\frac{\pi}{T_s}t}$$

Notes:

1. This theorem shows that under appropriate conditions, the signal  $x(t)$  equals, without approximation, the interpolation  $\tilde{x}(t)$  produced from its samples using the pulse  $p^*(t)$ .
2. Example: Suppose  $x(t) = 2 \cos(2\pi(3)t + .1) + 2 \cos(2\pi(5)t + .2)$ . Plot the spectrum. The theorem shows that interpolation from the samples of  $x(t)$  equals  $x(t)$  if we choose sampling rate  $f_s > 10$ .
3. Interpolator using  $p^*(t)$  is called "ideal interpolation". This particular pulse is often called a "sinc function" or "sinc pulse". Notice that it has infinite support and that due to the sine function in its numerator its value is zero at times  $\pm T_s, \pm 2T_s, \pm 3T_s, \dots$ . When  $t=0$ ,  $p^*(0) = \sin(0)/0$  appears to be undefined. However, since  $\sin(x)/x \rightarrow 1$  as  $x \rightarrow 0$ , we define  $p^*(0) = 1$ . A central portion of  $p^*(t)$  is shown below.

4. Example: Illustration of the interpolation of a set of samples using the sinc pulse:  
(show picture here)
5. This is a remarkable and surprising theorem. A complete derivation is beyond the scope of EECS 206, but is included in EECS 306. It requires the frequency domain analysis of aperiodic continuous-time signals via the "continuous-time Fourier transform". Later we'll have just a brief discussion about its derivation.  
The theorem is often called the Shannon Sampling Theorem, after UM alumnus Claude Shannon who published it in his pioneering 1948 paper on the theory of communications, which among other things made the sampling theorem widely known to engineers. The earliest versions of the theorem go back to 1847.
6. Let  $f_{\max}$  denote the highest frequency of any spectral component of the signal  $x(t)$ . If  $f_{\max} < \infty$ , then  $x(t)$  is said to be "bandlimited" because its bandwidth is finite. Moreover, we say " $x(t)$  is bandlimited to frequency  $f_{\max}$ ".

7. The Sampling Theorem applies to bandlimited signals, e.g. a finite sum of sinusoids. It shows that such signals can be perfectly recovered from their samples. Moreover, it indicates that the sampling frequency  $f_s$  need not grow without bound to obtain very good interpolations. We need only have

$$f_s > 2 f_{\max}$$

or equivalently

$$f_{\max} < \frac{f_s}{2}$$

$2f_{\max}$  is often called the "Nyquist frequency".

8. If a signal  $x(t)$  has  $f_{\max} = \infty$ , then it is not bandlimited and the sampling theorem does not apply. For example, a periodic square wave is not bandlimited. We'll discuss sampling nonbandlimited signals later.
9. The fact that the pulse  $p^*(t)$  has infinite support can make it difficult to build a system that implements ideal interpolation. For example, whereas zero-order hold and linear interpolation use just one and two samples, respectively, when producing the value of  $\tilde{x}(t)$  at any particular time  $t$ , the ideal interpolator uses an infinite number of samples.

In practice, few systems attempt to use ideal interpolation. Instead most use zero-order hold, linear interpolation, or some other simple scheme. Because of this, they generally need to use a sampling rate that is the larger than the Nyquist rate  $2f_{\max}$ . The ratio  $f_s/(2f_{\max})$  is sometimes called "the oversampling ratio".

If ideal interpolation is not commonly used, what then is the value of the sampling theorem? Its main value is in the understanding that it provides. For example, it tells us that good interpolation is possible only when  $f_s > 2f_{\max}$ .

10. It can be shown (e.g. in EECS 306) that the signal produced by the ideal interpolator, namely,

$$\tilde{x}(t) = \sum_{n=-\infty}^{\infty} x(nT_s) p^*(t - T_s),$$

is itself bandlimited to frequency  $f_s/2$  and that it is the only signal that is bandlimited to frequency  $f_s/2$  that passes through the samples. That is, any other interpolation of the samples has components at frequencies greater than  $f_s/2$ . Thus,  $\tilde{s}(t)$  is clearly the "smoothest" possible interpolation of the samples.

This is a very important property.

11. What's so special about  $2f_{\max}$ ? What goes wrong when  $f_s \leq 2f_{\max}$ ?

Example: Consider sampling the signal

$$x_0(t) = \cos(2\pi f_0 t + \phi)$$

with sampling rate  $f_s$  such that  $f_0 = 1.1 f_s$ . Notice that

$$f_s < f_0 = f_{\max} < 2f_{\max}.$$

Draw the signal, its samples, and the linear interpolation of the samples.

Notice that the interpolation looks like a sinusoid with a much lower frequency. Let us see what is happening. The sampled signal is

$$\begin{aligned}
 x_0[n] &= \cos(2\pi f_0 n T_s + \phi) \\
 &= \cos(2\pi(1.1)f_s n T_s + \phi) \\
 &= \cos(2\pi(1.1)n + \phi) && \text{since } f_s = 1/T_s \\
 &= \cos(2\pi(.1)n + \phi) && \text{since frequency } 2\pi(1.1) \text{ and} \\
 &&& \text{frequency } 2\pi(1.1) \text{ are equivalent}
 \end{aligned}$$

Now, observe that the samples of  $x_0(t)$  are exactly the same as the samples from the sinusoid  $x_1(t) = \cos(2\pi f_1 t + \phi)$  with the much lower frequency  $f_1 = 0.1 f_s$ :

$$\begin{aligned}
 x_1[n] &= \cos(2\pi f_1 n T_s + \phi) \\
 &= \cos(2\pi(.1)f_s n T_s + \phi) \\
 &= \cos(2\pi(.1)n + \phi) && \text{since } f_s = 1/T_s
 \end{aligned}$$

Thus we see that sampling produces  $x_0(t)$  and  $x_1(t)$  at the given sampling frequency produces  $x_0[n]$  and  $x_1[n]$  that are identical because they are sinusoids with equivalent frequencies.

Recalling the basic principles of interpolation, we recognize that any reasonable interpolator will attempt to produce the sinusoid  $x_1(t)$  because it fluctuates less. (Indeed, the sampling theorem indicates that the ideal interpolator would produce  $x_1(t)$  exactly, because  $f_s$  is more than twice as large as the frequency of all of its components.) Thus, we have the unpleasant situation that one signal  $x_0(t)$  is the input to the sampler, but a rather different signal  $x_1(t)$  comes out of the interpolator.

Example: Consider sampling the signal

$$x_0(t) = \cos(2\pi f_0 t + \phi)$$

with sampling rate  $f_s$  such that  $f_0 = 0.6 f_s$ . Notice that

$$f_s < 2f_0 = 2f_{\max}.$$

Draw the signal, its samples, and the linear interpolation of the samples.

Notice that the interpolation looks like a sinusoid with a lower frequency. Let us see what is happening. The sampled signal is

$$\begin{aligned}
 x_0[n] &= \cos(2\pi f_0 n T_s + \phi) \\
 &= \cos(2\pi(.6)f_s n T_s + \phi) \\
 &= \cos(2\pi(.6)n + \phi) && \text{since } f_s = 1/T_s
 \end{aligned}$$

Now, observe that the samples of  $x_0(t)$  are exactly the same as the samples from the sinusoid  $x_1(t) = \cos(2\pi f_1 t - \phi)$  with the lower frequency  $f_1 = 0.4 f_s$ :

$$x_1[n] = \cos(2\pi f_1 n T_s - \phi)$$

$$\begin{aligned}
&= \cos(2\pi(.4)f_s n T_s - \phi) \\
&= \cos(2\pi(.4)n - \phi) && \text{since } f_s = 1/T_s \\
&= \cos(-2\pi(.4)n + \phi) && \text{since } \cos(-\theta) = \cos(\theta) \\
&= \cos(2\pi(.6)n + \phi) && \text{since frequency } -2\pi(.4) \text{ and} \\
&&& \text{frequency } 2\pi(.6) \text{ are equivalent}
\end{aligned}$$

We see that sampling  $x_0(t)$  and  $x_1(t)$  produces  $x_0[n]$  and  $x_1[n]$  that are identical because they are sinusoids with equivalent frequencies. And as in the previous example, any reasonable interpolator will produce, at least approximately, the sinusoid  $x_1(t)$  because it has the lower frequency. (And the ideal sampling would produce  $x_1(t)$  exactly because  $f_s$  is more than twice as large as its frequency.)

12. Two continuous-time signals that have the same samples, such as in the previous two examples, are said to be "aliases" of each other. "Aliasing" is said to occur when, as in the previous example, a continuous-time signal  $x_0(t)$  is sampled, but a very different continuous-time signal  $x_1(t)$  is produced, at least approximately, by the interpolator. By "very" different we mean that the difference is not simply due to a crude interpolation, like zero-order hold, but is due to the fact that the interpolator has produced a signal that is, at least approximately, bandlimited to a lower frequency than the original signal. It is also common to say that  $x_0(t)$  has "aliased" to  $x_1(t)$ .

13. Examples of sinusoids and complex exponentials that are aliases of each other:

(a)  $x_0(t) = \cos(2\pi f_0 t + \phi)$  and  $x_1(t) = \cos(2\pi(f_0 + m f_s)t + \phi)$

where  $m$  is any positive or negative integer.

(b)  $x_0(t) = e^{j(2\pi f_0 t + \phi)}$  and  $x_1(t) = e^{j(2\pi(f_0 + m f_s)t + \phi)}$

where  $m$  is any positive or negative integer.

(c)  $x_0(t) = \cos(2\pi f_0 t + \phi)$  and  $x_1(t) = \cos(2\pi(m f_s - f_0)t - \phi)$

where  $m$  is any positive or negative integer. In this case, it is sometimes said that the frequencies of  $x_0(t)$  and  $x_1(t)$  are related by "folding".

14. From the above property we may deduce that any sinusoid  $x_0(t)$  with frequency greater than  $f_s/2$  has an alias  $x_1(t)$  with frequency less than  $f_s/2$ .

The following illustrates the higher frequencies that alias to a given frequency. It also indicates whether the aliasing results in the same phase or the negative of the phase.

15. Let us return to the question of what goes wrong when  $f_s < 2f_{\max}$  or, equivalently, when  $f_{\max} > f_s/2$ .

We begin by considering sinusoids. From the previous property, any sinusoid  $x_0(t)$  with frequency  $f_0 = f_{\max} > f_s/2$  has an alias with frequency  $f_1 = f_{\max} < f_s/2$ , which any reasonable interpolator will produce, at least approximately. This shows clearly what goes wrong.

Next, consider an arbitrary periodic signal  $x(t)$ . By the Fourier series theorem, this signal is a sum of sinusoidal components. We also note that sampling is a linear operation. Thus, the samples of the periodic signal are simply the sum of the samples from its sinusoidal components. If the signal has  $f_{\max} > f_s/2$ , then at least one sinusoidal component will suffer aliasing, and consequently the original signal  $x(t)$  suffers aliasing. In particular, the interpolator will produce, at least approximately, the sum of the aliased sinusoids, rather than the sum of the original sinusoids.

In summary, if a signal has  $f_{\max} > f_s/2$ , then the interpolator produces an alias with  $f_{\max} < f_s/2$ .

16. Derivation of the sampling theorem: Using Fourier series arguments like those in the previous note, one can show that if a periodic signal  $x(t)$  has  $f_{\max} < f_s/2$  (i.e. all spectral components have frequencies less than  $f_s/2$ ), then no other periodic signal with  $f_{\max} < f_s/2$  has the same samples. This indicates that if  $f_{\max} < f_s/2$ , then it should be possible to reconstruct the signal from its samples. However, to show that this can be done with the sinc pulse based interpolator requires continuous-time Fourier transform methods, which are beyond the scope of this class. They are included in EECS 306.

17. What happens if we sample exactly at the Nyquist rate, i.e. with  $f_s = 2f_{\max}$ ?

Aliasing might or might not occur. For example consider taking two samples per period from a sinusoid, which means  $f_s$  is exactly twice the frequency of the sinusoid. These samples can be taken at the zero crossings, in which case the sinusoid aliases to the all zero signal. Or they can be taken at the peaks, in which case aliasing does not occur. Or they can be taken at other times, in which case the sinusoid has an alias at the same frequency but a different phase.

(draw pictures of each of these cases)

18. What happens if a signal is bandlimited and we sample at too low a frequency?

In the case of a periodic signal and ideal interpolation, sampling and interpolation results reconstructs perfectly all spectral components at frequencies less than  $f_s/2$ , but all higher frequency spectral components alias to a frequency less than  $f_s/2$ .

(illustrate this)

19. How to sample a signal that is not bandlimited?

There's no perfect way. One must pick a sampling rate  $f_s$ . All spectral components at frequencies above  $f_s/2$  will alias to frequencies below  $f_s/2$ . If possible, one chooses  $f_s$  so large that the frequency components above  $f_s/2$  are very small.

(illustrate this)

If possible, one precedes the sampler with a "continuous-time filter" that eliminates

all frequency components above  $f_s/2$ . This reduces the interpolation MSE by approximately a factor of two. Continuous-time filters are discussed in EECS 306.

## 20. Sampling and interpolation for the signal recovery task.

In the signal recovery task, the signal  $x(t) = s(t) + n(t)$  is sampled with the goal of eventually producing an approximation  $\hat{s}(t)$  to  $s(t)$ , the desired part of the signal. Much of the remainder of the course will be devoted to designing *filters* as the digital processor.

Though we are not trying to reconstruct  $x(t)$ , it makes sense to sample it at a rate greater than  $2f_{\max}$  for  $x(t)$ , because then the samples contain all the information in  $x(t)$ . (From the samples, one could reconstruct  $x(t)$ .) It is not essential that one sample at a frequency significantly greater than  $2f_{\max}$ , but in some cases, this may simplify the processing that must be performed.

The digital-to-analog converter, which is the last step of the signal recovery system, is not actually reconstructing a signal from its samples. Rather, it is constructing a signal  $\hat{s}(t)$  from samples  $\hat{s}[n]$  created by a digital processor. The interpolation used by the digital-to-analog converter could be zero-order hold, linear interpolation, ideal interpolation, or some other form of interpolation.

If ideal interpolation is chosen, then  $\hat{s}(t)$  is determined by the formula

$$\hat{s}(t) = \sum_{n=-\infty}^{\infty} \hat{s}[n] p^*(t-nT_s)$$

There is also, sometimes, a shortcut to finding  $\hat{s}(t)$ . In particular, if  $\hat{s}[n]$  happens to be a sinusoid, e.g.

$$\hat{s}[n] = A \cos(\hat{\omega}n + \phi), \quad 0 \leq \hat{\omega} \leq \pi$$

then we know that the ideal interpolator will produce the unique continuous-time signal that is bandlimited to frequency  $f_s/2$  and has  $\hat{s}[n]$  as its samples. What is this signal? It is easy to see by inspection that the following signal has these two properties:

$$A \cos(\hat{\omega}f_s t + \phi).$$

Thus, it must be the output  $\hat{s}(t)$  of the ideal interpolator.

This method can also be applied when the discrete-time signal is the sum of sinusoids, by applying it separately to each sinusoidal component. It can also be applied to arbitrary periodic signals, because by the DFT Theorem, any periodic signal is the sum of sinusoids.

## 21. Sampling for signal detection.

In the signal detection problem, we sample the signal  $x(t) = s(t) + n(t)$  with the goal of making a decision about  $s(t)$  based on the samples. The system does not output a continuous-time signal. As in the signal recovery problem, it makes sense to sample  $x(t)$  at a rate greater than  $2f_{\max}$ , because in this case, the samples contain all the information that was originally in  $x(t)$ . Sometimes sampling at a significantly higher rate simplifies the processing that must be done.
